Parallel-displaced π - π stacking interactions were investigated experimentally using two different host-guest model systems with Rebek imide-type receptors **1** or **2** and 2,6-di(isobutyramido)pyridine ligand **3** (Figure 1).^[1,2]

Guest **3** forms a triple H-bonding array to the imide moieties of receptors **1** or **2**. This allows for a parallel stacking geometry between the pyridine ring in **3** and the aromatic platform of **1** or **2** at different displacement, as confirmed by comprehensive structural analysis in solution and in solid state. In complex **1**·**3**, partial overlap between the pyridine core of **3** and the *para*-substituent R¹ is generated by a short ethyne-1,2-diyl spacer and enables direct, through space interactions. Any substituent had a stabilizing effect on the stacking interaction, independent of its electronic nature. In complex **2**·**3**, the elongated buta-1,3-diyne-1,4-diyl spacer prevents local, direct interactions between guest **3** and *para*-substituent R². Here, the electronic influence of the substituent on the aromatic platform affected the stacking strength crucially.

Changing the distance between substituent and intermolecularly interacting aromatic ring results in a fundamentally different substituent effect on parallel π - π stacking interactions.
